

SUBSTANCE EXHIBITING ANTIDEPRESSANT PROPERTY

Field of the Invention

This invention relates to medicine, more particularly to pharmacology,
5 and specifically to antidepressants selectively improving depressed mood
with dominating asthenic emotions manifested as melancholy, apathy,
volition diminution, anxiety, fears, especially in cases when changed mood is
relatively fixed and stable within not only days or weeks, but even months
and years, and has effects on behavior, thinking, activity and physiological
10 functions of the organism.

Description of the Prior Art

The standard antidepressant, which is widely used for treatment of
depressed moods, is amitriptyline (5-(3-dimethylaminopropylidene)-10, 11-
15 dihydrodibenzocycloheptene hydrochloride (Mashkovsky M.D., Medications
// Pharmacotherapy Aid for Physicians, P. 1, Moscow, "Medicina"
Publishers, 1988, p. 90-96).

Amitriptyline, as a standard medication, has the following
disadvantages: presence of sedative and clearly manifested anticholinergic
20 effects, relatively slow therapeutic effect, as well as direct dose-dependence
effect requiring to continuously increase a dose, if applied in a course
treatment, gradually reduce the dose after withdrawal of the medication,
limitations in professions requiring attention and quick decision-making.

Summary of the Invention

25 The objective of this invention is to develop a medication having a
high antidepressant activity combined with the absence of the adverse
reactions peculiar to amitriptyline.

In compliance with the said objective it is possible to obtain technical results causing an increased antidepressant effect after one dose, absence of sedative and cholinergic effects, avoidance of tolerance and the withdrawal syndrome at course treatment, removal of limitations for professional activities.

The said technical results can be achieved due to the fact that N-carbamoyl-methyl-4-phenyl-2-pyrrolidone (phenotropyl) is used as the antidepressant agent.

Phenotropyl is known as a substance having hypotensive activity (SU № 797219, A 61 K 21/40); a substance having nootropic activity (RU № 2050851, A 61 K 31/40); an antiischemic agent (RU № 2183117, A 61 K 31/405).

Antidepressant properties of phenotropyl are unknown. Phenotropyl has not been used as a medication used for treatment of depressions.

Detailed Description of the Preferred Embodiment

The study of the phenotropyl antidepressant activity has been carried out in accordance with the Guidebook for Experimental (Preclinical) Studies of New Pharmaceuticals of the RF Ministry of Public Health (Andreeva N.I., the Methodical Guidelines for Studying Antidepressant Activity of Pharmaceuticals, ZAO IIA "Remedium", 2000, p. 121-125).

The study results have been processed statistically. The average values and their standard deviations for each group have been calculated. The reliability of the differences between the experimental and the control groups has been checked by a dispersion analysis and the Student's method (Borovikov V.P., Statistics: the art of computerized analysis of data. For professionals // Saint-Petersburg – Piter - 2001. 247 p.).

Example 1. A study of the antidepressant action of phenotropyl

with the use of the Porsolt method of behavioral despair (helplessness).

The Porsolt method of behavioral despair (helplessness) (Porsolt R.D., Anton G., Blavet N. et al. Behavioral despair in rats: a new model sensitive to antidepressant treatment // *Europ. J. Pharmacol.* 1978-v.47.-p. 379-391) is the basic model for assessing antidepressants (Andreeva N.I., Андреева Н.И. the Methodical Guidelines for Studying Antidepressant Activity of Pharmaceuticals, // *Guidebook for Experimental (Preclinical) Studies of New Pharmaceuticals of the RF Ministry of Public Health.- ZAO IIA "Remedium".- 2000.- p. 121-125*). The studies have been conducted on white outbred male rats having the weight of 230-250 grams. The animals have been put into a water reservoir having 40 cm in diameter and the depth of 60 cm, for the rats cannot either run out of the reservoir or find a support in it. The water temperature has been maintained at the level of 25 °C, the experiments have been conducted within the period from 12 A.M. to 4 P.M. After coming into water the animals begin displaying energetic motion activity aimed at finding a way out of the aversive (troublesome) situation, but then they stop their attempts and take a typical position in the water, while being fully immovable or making insignificant motions necessary for keeping their heads over the water surface. The depressive condition intensity rate in this test is the duration of immobility. The immobility condition has been assessed visually, determining its duration within 10 minutes of the observations. Substances having antidepressant activity alleviate this condition by reducing the immobility time.

The studies have been conducted using animals divided into groups. The animals from the experimental groups have received single doses of phenotrotyl in the amounts of 25, 50 and 100 mg/kg or the standard amitriptyline medication in the amount of 10 mg/kg (ampoule solution made by Spofa, the Czech Republic) in the volume corresponding to the dose. The

animals from the control group have received distilled water in the same dosage. All the substances have been given intragastrically 40 minutes before the an experiment.

It has been established that during the behavioral despair test the control group animals, after being put into a water reservoir and making active attempts to come out of the aversive situation, have revolutioned into the immobility state reflecting their depressive condition. Phenotrotyl in single doses of 50 and 100 mg/kg has a pronounced antidepressant effect during this test (see Table 1). The medication effect coming after doses of 50 and 100 mg/kg has been displayed as statistically reliable reduction (by 1.6 times) in the time of immobility of the rats, as compared to the control group. Amitriptyline, as the standard antidepressant, has also reliably reduced the immobility time.

Thus, judging by its antidepressant effect in the behavioral helplessness test, phenotrotyl has activity similar to that of amitriptyline.

Example 2. The study of the phenotrotyl antidepressant action with the use of the method of involuntary swimming with freely moving wheels according to Nomura.

The method of involuntary swimming in a reservoir with freely moving wheels (Nomura S., Shimizu J., Kinjo M. et al. A new behavioral test for antidepressant drugs// Eur. J. Pharmacol.–1982.–v.83.–N 3–4.–p. 171-175) is widely used for assessing the action of antidepressant agents. The installation is a reservoir having dimensions of 64x30x42 cm and divided into four equal sections where wheels are located. The reservoir is filled with water at the temperature of 25 °C, coming to the medium line of the wheels. The studies have been conducted with white outbred male rats having the weight from 230 to 250 grams. The rats have been put into each section in the position where their heads are opposite to the wheels, and then the wheel speed

has been recorded for 10 minutes with the use of electromechanical counters. The number of wheel revolutions made by the rat for 10 minutes is recorded.

This study has been conducted with animals from different groups. The rats from the experimental groups have received single doses of phenotrotyl in the amounts of 25, 50 and 100 mg/kg or the standard amitriptyline medication in the amount of 10 mg/kg (ampoule solution made by Spofa, the Czech Republic) in the volume corresponding to the dosage. The animals from the control group have received distilled water in the same dosage. All the substances have been given intragastrically 40 minutes before the an
10 experiment.

It has been established that during the test of involuntary swimming in the reservoir with wheels the rats from the control group first try to go out of the water, but since the wheels are moving freely, their attempts are not successful, and the animals soon give up, "hovering" in the water. The
15 number of wheel revolutions for 10 minutes of observation is $58,8 \pm 14,3$ (see Table 2). After a single dose of phenotrotyl given to the rats, their manifestations of depressive conditions have been reduced, which has been evidenced by the fact that the animals begin revolutioning the wheels actively. Thus, after introducing a phenotrotyl dose of 100 mg/kg, the rats
20 have made $121,8 \pm 23,7$ revolutions for 10 minutes of observations. The evidence of the antidepressant effect of phenotrotyl in doses of 25, 50 and 100 mg/kg have been statistically reliable, as compared to the data obtained for the control group. Amitriptyline, similarly to phenotrotyl, also increases the rat activity, reliably increasing the number of wheel revolutions.

25 Thus, judging by the results of the involuntary swimming test, phenotrotyl has pronounced antidepressant action and is not inferior to amitriptyline as to its activity.

Example 3. The study of the phenotrotyl antidepressant activity

with the use of the reserpine depression method.

The method of reserpine depression according to Bernardi (Bernardi D., Paglialunga S., Jori A. Peripheral and central components in the hyperthermic effect of desipramine in rezerpinized rats // J. Pharm. Pharmacol., 1968, vol. 20, p. 204-209) is one of the basic models for assessing antidepressants in studies of new pharmaceuticals. The studies have been conducted with white outbred male rats having the weight from 200 to 240 grams. Reserpine has been introduced intraperitoneally, as a single dose of 2.5 mg/kg 2 hours before the introduction of phenotrotyl (intraperitoneally, single doses of 25, 50, 100 and 200 mg/kg) and 3 hours before starting the study. The animals from the control group have received intraperitoneally distilled water only in the same volumes as the animals from the experimental groups. The antidepressant activity of phenotrotyl has been assessed by its effect on sedation (suppression of the orientation and motion activity), intensity of ptosis and diarrhea, which have been caused by reserpine in the rats.

The orientation and motion activity of the animals has been studied for three minutes in a special activity meter (Varimex). The intensity of ptosis and diarrhea has been assessed on the standard 4-point scale (Mashkovsky M. D., Andreeva N.I., Polezhaeva A.I. Pharmacology of Antidepressants. Moscow, Medicine Publishers, 1983, p. 194-199).

The study results, as presented in Table 3, show that a single dose of phenotrotyl prominently antagonizes the reserpine syndrome: the intensity of ptosis is reliably reduced by 1.4 and 1.8 times, respectively, after introducing doses of 50, 100 and 200 mg/kg; the diarrhea intensity is reliably reduced by 1.7 times after a dose of 50 mg/kg, by 2.4 times after a dose of 100 mg/kg, and by 2.2 times after a dose of 200 mg/kg; the orientation and motion activity of the animals is increased at the background of phenotrotyl doses of

25 and 50 mg/kg and reliably corresponds to the control level when administering doses of 100 and 200 mg/kg.

Thus, judging by the results of the reserpine depression test, phenotrotyl has pronounced antidepressant activity and displays the motion
5 activating component.

Example 4. The study of the phenotrotyl antidepressant activity by the haloperidol catalepsy method.

As one of the indicators for antidepressant antagonism in relation to depriving effects of neuroleptics, neuroleptic-induced catalepsy is used. The
10 maintenance of catalepsy in animals is assessed by their ability to maintain set or unusual poses for a definite time (Morpurgo C. Effects of antiparkinson drugs on phenothiazine induced catatonia reaction // Arch. Int Pharmacodyn., 1962, vol. 137 № 1-2, p. 84-94). Reduction or prevention of catalepsy is one of the factors showing antidepressant activity in studied substances.

15 The studies have been conducted with white outbred male mice having the weight from 18 to 24 grams. Haloperidol is introduced intraperitoneally in a single dose of 0.5 mg/kg. Phenotrotyl has been introduced intraperitoneally in doses of 50, 100 and 200 mg/kg in 15 minutes after the introduction of haloperidol. The catalepsy intensity has been assessed by time
20 (in seconds) of keeping the animals in an uncomfortable pose where their front legs have been put onto a bar having the height of 4 cm, in 60, 120 and 180 minutes after introducing the said medications. It is shown in Table 4 that phenotrotyl clearly antagonizes haloperidol-induced catalepsy. Phenotrotyl in doses of 50 and 100 mg/kg fully prevents the development of
25 catalepsy in 60 minutes and reduces its development level 3.2 and 14 times, respectively, in 120 minutes after the introduction of the medication, and 13.2 times with a dose of 50 mg/kg in 180 minutes, fully stopping its development in 180 minutes with a dose of 100 or 200 mg/kg.

The study results show that, according to the haloperidol catalepsy test, phenotropyl has antidepressant activity.

Example 5. The study of the phenotropyl antidepressant activity under the Hamilton rating scale during clinical studies.

5 The Hamilton rating scale for primary depressive illness (Hamilton M. Development of a rating scale for primary depressive illness // Br J Soc Clin Psychol. 1967 Dec;6(4):278-96) is one of the most widely used scales for assessing depression in the clinical practice.

10 The material for clinical studies has comprised two homogenous groups of patients having depressive illnesses (40 persons) aged 20 – 42, out of which 20 patients have taken amitriptyline in the daily dose of 75 mg (25 mg three times a day), and 20 patients have taken phenotropyl in the daily dose of 100 mg as a single dose in the morning time. For a comparative study of the medications antidepressant activity the patients have been enlisted for
15 the study according to the following criteria: the informed consent is available, a light or moderate depressive episode (F32.0 и F32.1 according to MCB-10) is present, the total score under the Hamilton rating scale is not lower than 18, no contraindications to taking amitriptyline and phenotropyl. The patients have been relatively uniformly assigned to the said groups
20 according to meaningful factors, such as sex and age, time for which the condition exists and syndrome characteristics. The condition existence time varied from 1 to 2 years. The therapy efficiency has been assessed on the basis of a degree of reduction of the total score under the Hamilton scale, namely: full effect – reduction by more than 50%; partial reduction – from 25
25 to 50%; no effect – reduction by less than 25%. The condition of the patients has been assessed during the background studies and at each 7th day of the therapy for the whole 6 weeks of the therapy. In total, seven examinations have been carried out. The comparative data on the general efficiency of the

medications, as given in Table 5, evidence a rather quick reduction of the depressive illness psychopathological symptoms in the process of administering phenotropyl and amitriptyline. However, the antidepressant effect of phenotropyl has been more pronounced on the 7th and 14th days of the therapy. The full reduction has been attained in 25% and 40% of the patients, respectively. The full reduction is attained in 70% and 80% of the patients on the 21st and 28th days of the therapy, i.e., two weeks earlier than for the amitriptyline therapy. From the 28th day of the therapy the number of the patients experiencing the maximum effect has not been changed either on the 35th or the 42nd days of the therapy. Out of 20% of the patients experiencing a partial reduction of the depressive symptoms, 15% have been patients with the reduction from 25% to 50%, and 5% - patients with the reduction by less than 25%. At the background of taking phenotropyl no cases of sedative and cholinergic effects have been recorded, the workability has been improved, asthenia and inhibition have been corrected.

The clinical study results show that phenotropyl has pronounced antidepressant activity according to the Hamilton rating scale of depressive illness.

The conducted studies evidence the fact that phenotropyl has pronounced antidepressant activity in the conditions required for the reserpine depression method and the haloperidol catalepsy method, in the conditions required for the behavioral despair method and the involuntary swimming method, as well as in the conditions of a clinical study under the Hamilton rating scale of depressive illness. The medication effect has been observed for doses of 25, 50, 100 and 200 mg/kg during the experimental studies in animals. The clinical studies of phenotropyl in the dose of 100 mg show its high antidepressant activity in light depressive conditions and depressions of moderate degree. Also, the advantage of phenotropyl is that it

may be taken once a day. The course administration of this medication does not induce tolerance and the withdrawal syndrome. As to its antidepressant activity, phenotrotyl is not inferior to the standard amitriptyline medication. Phenotrotyl is of interest for psychiatric and neurological practice as well as
5 for the emergency medicine and the accident medicine.

Industrial Applicability

This invention is industrially applicable and may be most successfully used as antidepressants selectively improving the condition of a depressive mood with dominating asthenic emotions manifested as melancholy, apathy,
10 volition diminution, anxiety, fears, especially in cases when changed mood is relatively fixed and stable within not only days or weeks, but even months and years, and has effects on behavior, thinking, activity and physiological functions of the organism. The inventive substance does not require any new technologies or equipment.

Table 1.

The effect of phenotrotyl after single introduction on the time of immobility in the conditions of the behavioral despair method according to Porsolt

Substances	Dose, mg/kg	Time of immobility, seconds
Control	-	342.3 ± 58.1
Phenotrotyl	25	275.5 ± 84.2
Phenotrotyl	50	185.7 ± 49.5*

CLAIMS

N-carbamoyl-methyl-4-phenyl-2-pyrrolidone as a substance displaying
nootropic activity.

ABSTRACT

The invention relates to medicine, more specifically to antidepressant pharmacology which selectively improves a diminished mood dominated by asthenic emotions. The inventive antidepressant substance is embodied in the
5 form of N-carbamoyl-methyl-4-phenyl-2-pyrrolidone. Said invention increases the evidence of antidepressant effect after a single dose, prevents sedative and cholinergic effects, avoids the development of a tolerance and withdrawal syndrome during a course of application and allows for the unrestricted use of said substance for professional activity.
